Network Communication and Remote Procedure Calls

جامعة الملك عبدالله للعلوم والتقنية King Abdullah University of Science and Technology

CS 240: Computing Systems and Concurrency Lecture 3

Marco Canini

Credits: Michael Freedman and Kyle Jamieson developed much of the original material.

Context and today's outline

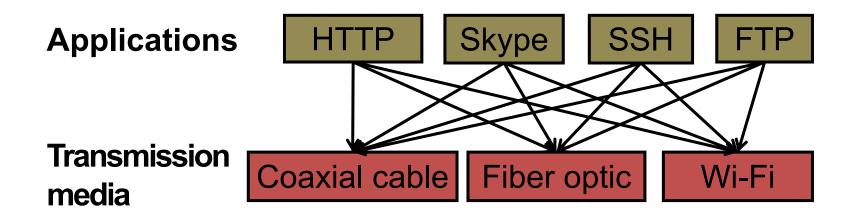

• A *distributed system* is many cooperating computers that appear to users as a single service

- Today— How can processes on different cooperating computers exchange information?
- 1. Network Sockets
- 2. Remote Procedure Call

The problem of communication

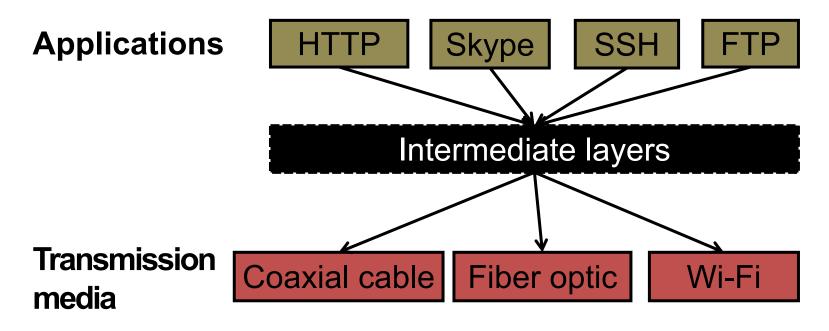

- Process on Host A wants to talk to process on Host B
 - A and B must agree on the meaning of the bits being sent and received at many different levels, including:
 - How many volts is a 0 bit, a 1 bit?
 - How does receiver know which is the last bit?
 - How many bits long is a number?

The problem of communication

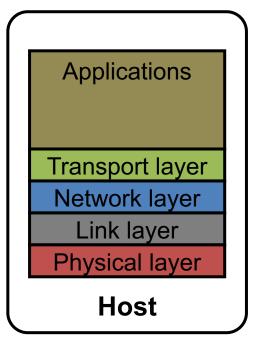

- Re-implement every application for every new underlying transmission medium?
 - Change every application on any change to an underlying transmission medium?
- **No!** But how does the Internet design avoid this?

Solution: Layering

- Intermediate *layers* provide a set of abstractions for applications and media
- New applications or media need only implement for intermediate layer's interface

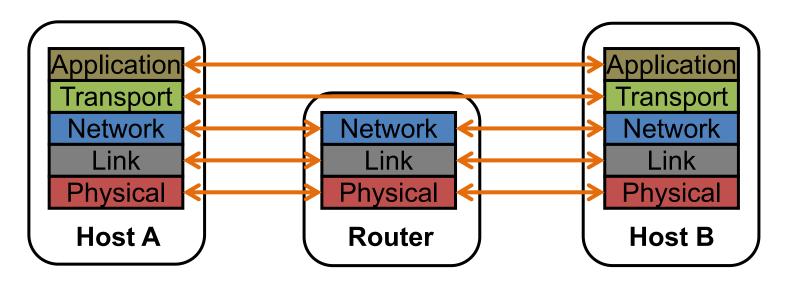

Layering in the Internet

- Transport: Provide end-to-end communication between processes on different hosts
- Network: Deliver packets to destinations on other (heterogeneous) networks
- Link: Enables end hosts to exchange atomic messages with each other
- Physical: Moves bits between two hosts connected by a physical link

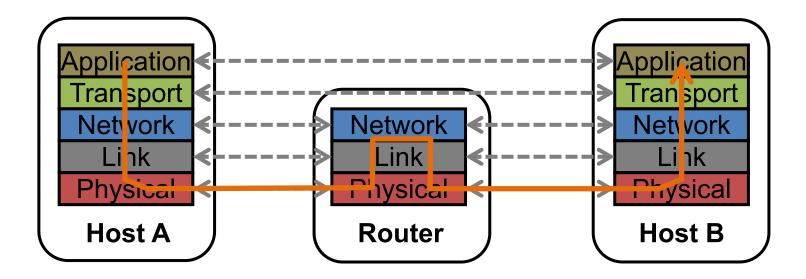

Logical communication between layers

- How to forge agreement on the meaning of the bits exchanged between two hosts?
- Protocol: Rules that governs the format, contents, and meaning of messages
 - Each layer on a host interacts with its peer host's corresponding layer via the protocol interface

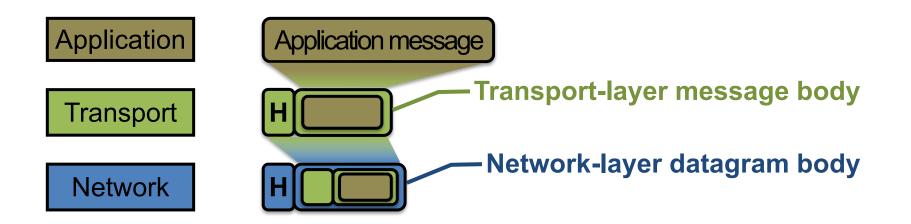

Physical communication

- Communication goes down to the physical network
- Then from **network** peer to peer
- Then up to the **relevant application**

Communication between peers

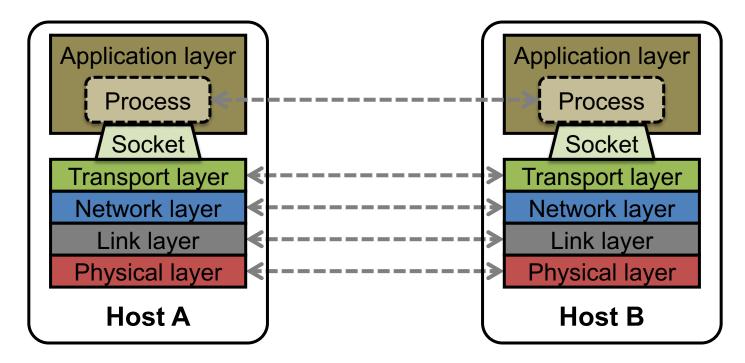

- How do peer protocols coordinate with each other?
- Layer attaches its own *header* (H) to communicate with peer
 - Higher layers' headers, data encapsulated inside message
 - Lower layers don't generally inspect higher layers' headers

Network socket-based communication

- Socket: The interface the OS provides to the network

 Provides inter-process explicit message exchange
- Can build distributed systems atop sockets: send(), recv()
 e.g.: **put(key,value)** → message

Network sockets: Summary

- **Principle of transparency: Hide** that resource is physically distributed across multiple computers
 - Access resource same way as locally
 - Users can't tell where resource is physically located

Network sockets provide apps with **point-to-point communication** between processes

• **put(key,value)** → message with sockets?

```
// Create a socket for the client
if ((sockfd = socket (AF INET, SOCK STREAM, 0)) < 0) {
  perror("Socket creation");
 exit(2);
}
// Set server address and port
memset(&servaddr, 0, sizeof(servaddr));
servaddr.sin family = AF INET;
servaddr.sin addr.s addr = inet addr(argv[1]);
Servaddr.gin port. = htong(SFPN, PORT) . // to biggordian.
// Es Sockets don't provide transparency
if (connect(sockfd, (struct sockaddr *) & servaddr,
            sizeof(servaddr)) < 0) {</pre>
  perror("Connect to server");
  exit(3);
}
```

// Transmit the data over the TCP connection
send(sockfd, buf, strlen(buf), 0);

Today's outline

- 1. Network Sockets
- 2. Remote Procedure Call
- 3. Threads

Why RPC?

The typical programmer is trained to write single-threaded code that runs in one place

- Goal: Easy-to-program network communication that makes client-server communication transparent
 - Retains the "feel" of writing centralized code
 - Programmer needn't think about the network

Course programming assignments use RPC

What's the goal of RPC?

- Within a single program, running in a single process, recall the well-known notion of a procedure call:
 - Caller pushes arguments onto stack,
 - jumps to address of *callee* function
 - Callee reads arguments from stack,
 - executes, puts return value in register,
 - returns to next instruction in caller

RPC's Goal: To make communication appear like a **local** procedure call: **transparency** for procedure calls

Historical note

- Seems obvious in retrospect, but RPC was only invented in the '80s
- See Birrell & Nelson, "Implementing Remote Procedure Call" ... or
- Bruce Nelson, Ph.D. Thesis, Carnegie Mellon University: Remote Procedure Call., 1981

RPC issues

1. Heterogeneity

- Client needs to rendezvous with the server
- Server must **dispatch** to the required function
 - What if server is **different** type of machine?

2. Failure

- What if messages get dropped?
- What if client, server, or network fails?

3. Performance

- Procedure call takes \approx 10 cycles \approx 3 ns
- RPC in a data center takes \approx 10 µs (10³ × slower)
 - In the wide area, typically $10^6 \times$ slower

Problem: Differences in data representation

- Not an issue for **local** procedure call
- For a remote procedure call, a **remote machine may:**
 - Represent data types using different sizes
 - Use a different byte ordering (endianness)
 - Represent floating point numbers differently
 - Have different data alignment requirements
 - e.g., 4-byte type begins only on 4-byte memory boundary

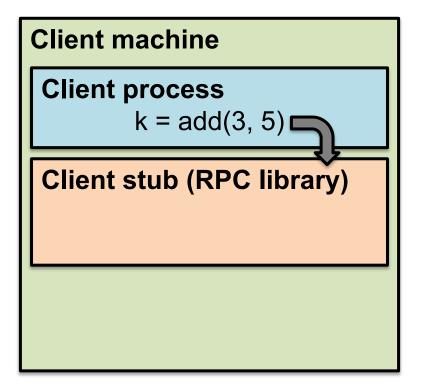

Problem: Differences in programming support

- Language support varies:
 - Many programming languages have no inbuilt concept of remote procedure calls
 - *e.g.*, C, C++, earlier Java: won't generate stubs
 - Some languages have support that enables RPC
 - e.g., Python, Haskell, Go

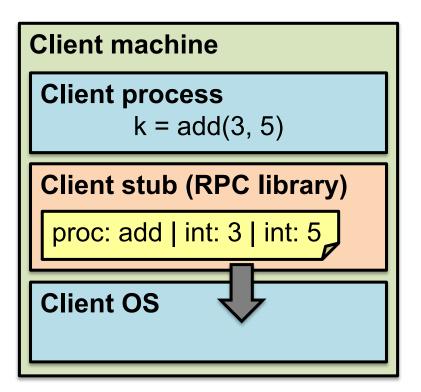

Solution: Interface Description Language

- Mechanism to pass procedure parameters and return values in a machine-independent way
- Programmer may write an *interface description* in the IDL
 - Defines API for procedure calls: names, parameter/return types
- Then runs an *IDL compiler* which generates:
 - Code to *marshal* (convert) native data types into machineindependent byte streams
 - And vice-versa, called *unmarshaling*
 - Client stub: Forwards local procedure call as a request to server
 - Server stub: Dispatches RPC to its implementation

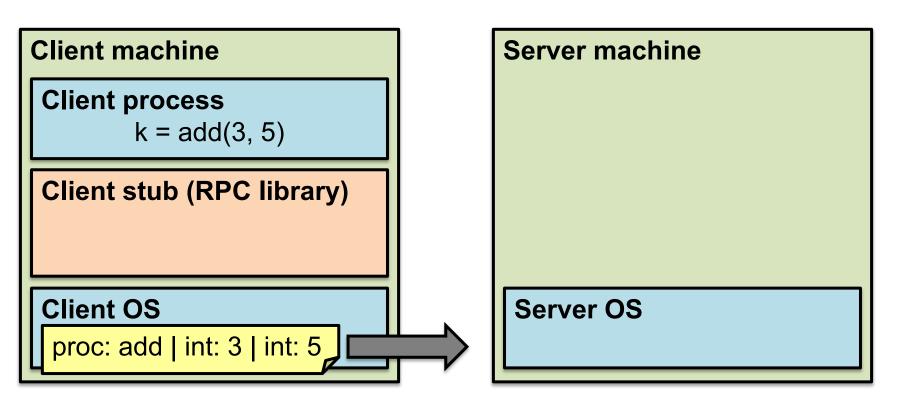

1. Client calls stub function (pushes params onto stack)

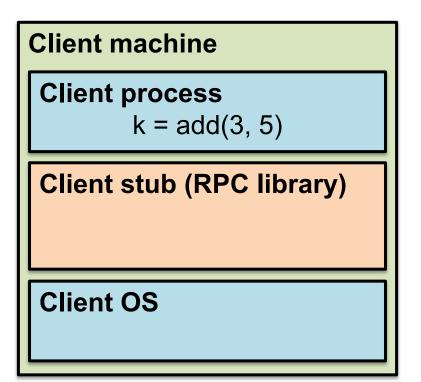

- 1. Client calls stub function (pushes params onto stack)
- 2. Stub marshals parameters to a network message

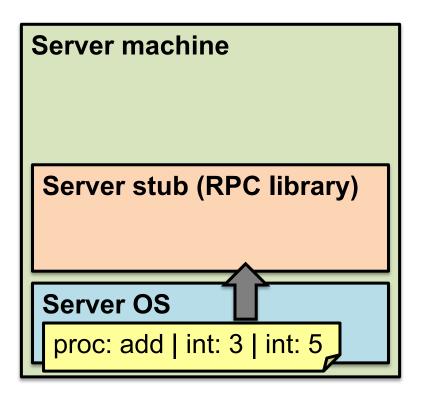

- 2. Stub marshals parameters to a network message
- 3. OS sends a network message to the server

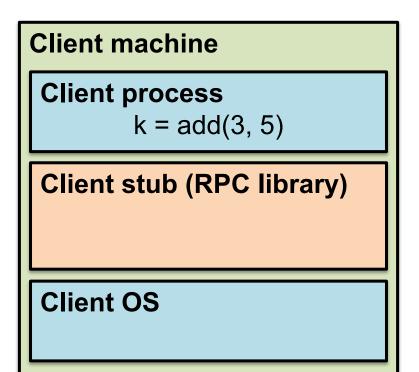

- 3. OS sends a network message to the server
- 4. Server OS receives message, sends it up to stub

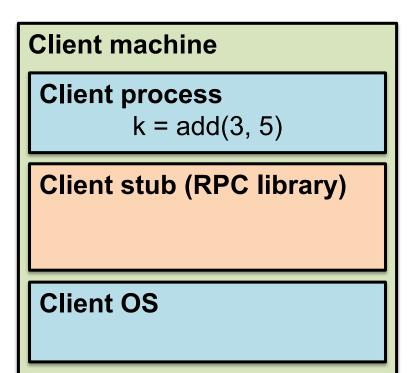

- 4. Server OS receives message, sends it up to stub
- 5. Server stub unmarshals params, calls server function

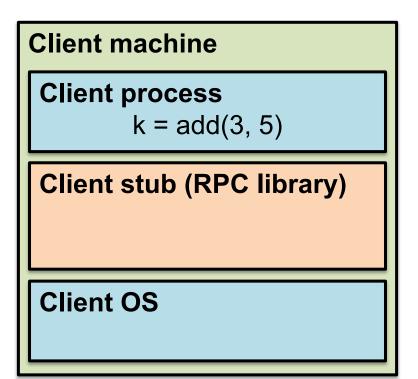

Server machine		
Server process Implementation of add		
Server stub (RPC lib ry)		
proc: add int: 3 int: 5		
Server OS		

- 5. Server stub unmarshals params, calls server function
- 6. Server function runs, returns a value

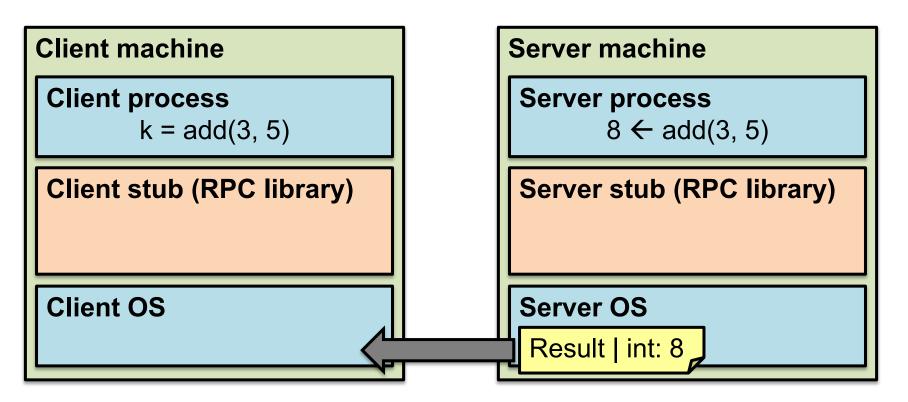

Server machine
Server process 8 ← add(3, 5)
Server stub (RPC library)
Server OS

- 6. Server function runs, returns a value
- 7. Server stub marshals the return value, sends msg

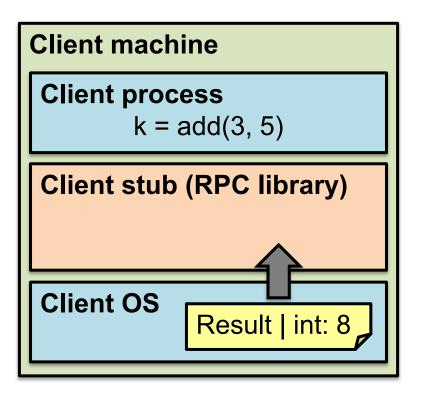

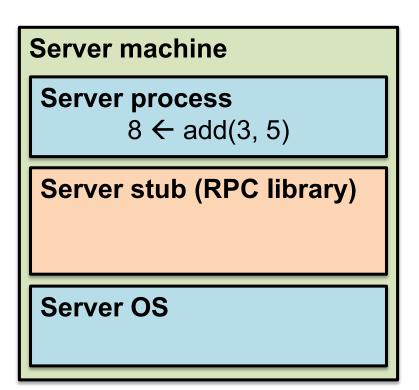

Server machine		
Server process $8 \leftarrow add(3, 5)$		
Server stub (RPC library)		
	Result int: 8	
Server OS		

- 7. Server stub marshals the return value, sends msg
- 8. Server OS sends the reply back across the network

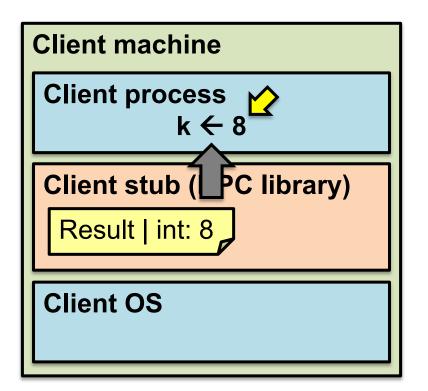

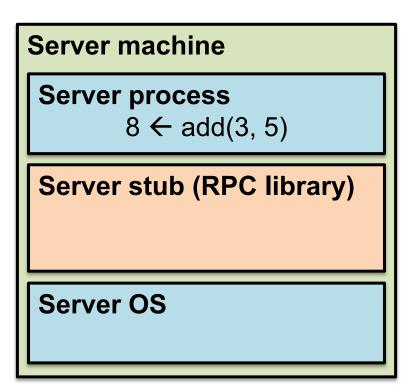

- 8. Server OS sends the reply back across the network
- 9. Client OS receives the reply and passes up to stub

- 9. Client OS receives the reply and passes up to stub
- 10. Client stub unmarshals return value, returns to client

The server stub is really two parts

Dispatcher

- Receives a client's RPC request
 - Identifies appropriate server-side method to invoke

• Skeleton

- Unmarshals parameters to server-native types
- Calls the local server procedure
- Marshals the response, sends it back to the dispatcher

• All this is hidden from the programmer

- Dispatcher and skeleton may be integrated
 - Depends on implementation

Today's outline

1. Message-Oriented Communication

2. Remote Procedure Call

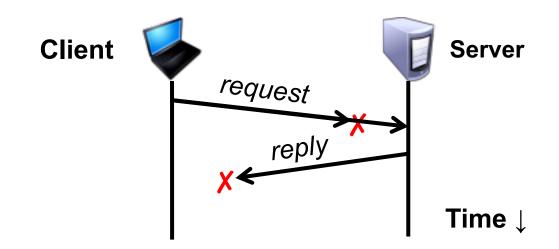

- Rendezvous and coordination
- Failure
- Performance

What could possibly go wrong?

- 1. Client may crash and reboot
- 2. Packets may be dropped
 - Some individual packet loss in the Internet
 - Broken routing results in many lost packets
- 3. Server may crash and reboot
- 4. Network or server might just be very slow

All these may look the same to the client...

Failures, from client's perspective

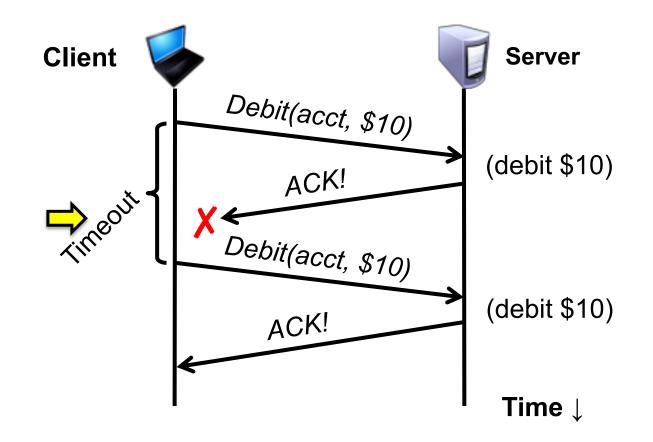

The cause of the failure is hidden from the client!

At-Least-Once scheme

- **Simplest** scheme for handling failures
- 1. Client stub waits for a response, for a while
 - Response takes the form of an *acknowledgement* message from the server stub
- 2. If no response arrives after a fixed *timeout* time period, then client stub **re-sends the request**
- Repeat the above a few times
 - Still no response? Return an error to the application

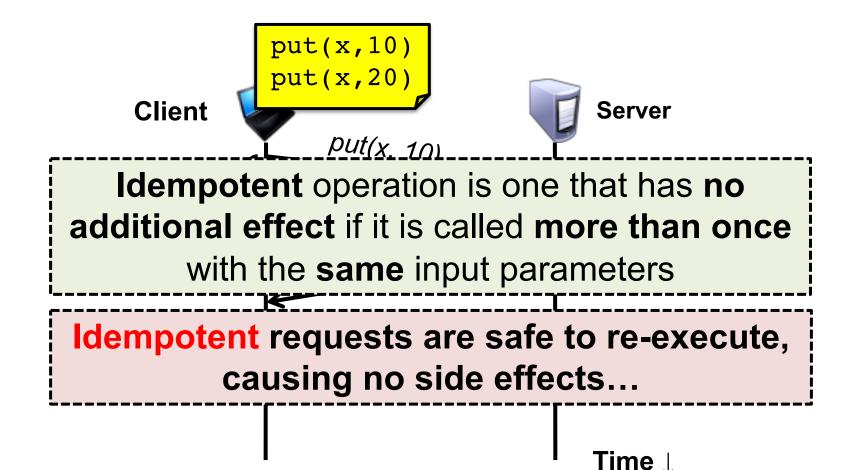

At-Least-Once and side effects

• Client sends a "debit \$10 from bank account" RPC

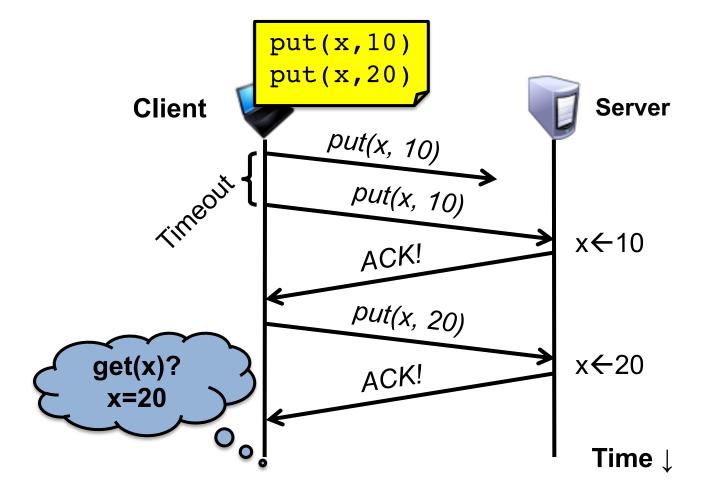

At-Least-Once and writes

put(x, value), then get(x): expect answer to be value

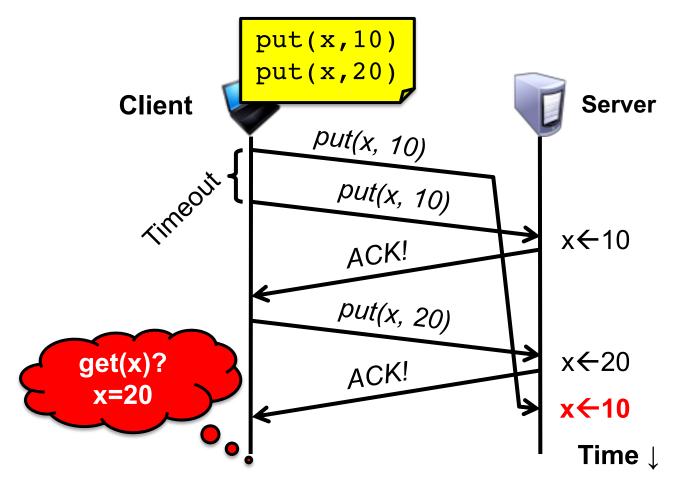

At-Least-Once and writes

put(x, value), then get(x): expect answer to be value

At-Least-Once and writes

Consider a client storing key-value pairs in a database
 – put(x, value), then get(x): expect answer to be value

So is At-Least-Once ever okay?

 Yes: If they are read-only operations with no side effects – *e.g.*, read a key's value in a database

- Yes: If the application has its own functionality to cope with duplication and reordering
 - You will need this in Assignments 3 onwards

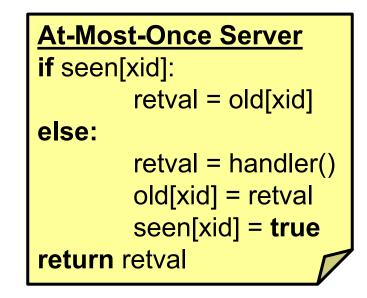

At-Most-Once scheme

Idea: server RPC code detects duplicate requests
 – Returns previous reply instead of re-running handler

- *How to detect a duplicate request?*
 - **Test:** Server sees same function, same arguments twice
 - No! Sometimes applications legitimately submit the same function with same augments, twice in a row

At-Most-Once scheme

- *How to detect a duplicate request?*
 - Client includes unique *transaction ID* (*xid*) with each one of its RPC requests
 - Client uses **same xid** for retransmitted requests

At Most Once: Providing unique XIDs

- How to ensure that the xid is unique?
- 1. Combine a unique client ID (*e.g.*, IP address) with the current time of day
- 2. Combine unique client ID with a sequence number
 - Suppose the client crashes and restarts. Can it reuse the same client ID?
- 3. Big random number (probabilistic, not certain guarantee)

Today's outline

1. Message-Oriented Communication

2. Remote Procedure Call

- Rendezvous and coordination
- Failure
- Performance

At-Most-Once: Discarding server state

- Problem: seen and old arrays will grow without bound
- Observation: By construction, when the client gets a response to a particular xid, it will never re-send it
- Client could **tell** server "I'm done with xid x delete it"
 - Have to tell the server about each and every retired xid
 - Could **piggyback** on subsequent requests

At-Most-Once: Discarding server state

- Problem: seen and old arrays will grow without bound
- Suppose xid = (unique client id, sequence no.)
 e.g. (42, 1000), (42, 1001), (42, 1002)
- Client includes "seen all replies ≤ X" with every RPC
 Much like TCP sequence numbers, acks
- How does the client **know** that the server received the information about retired RPCs?
 - Each one of these is cumulative: later seen messages subsume earlier ones

At-Most-Once: Concurrent requests

- **Problem:** How to handle a duplicate request while the original is still executing?
 - Server doesn't know reply yet. Also, we don't want to run the procedure twice

Idea: Add a pending flag per executing RPC
 – Server waits for the procedure to finish, or ignores

At Most Once: Server crash and restart

• **Problem:** Server may crash and restart

• Does server need to write its state (seen, old) to disk?

- Yes! On server crash and restart:
 - If old[], seen[] arrays are only in memory:
 - Server will forget, accept duplicate requests

Go's net/rpc is at-most-once

- Opens a TCP connection and writes the request
 - TCP may retransmit but server's TCP receiver will filter out duplicates internally, with sequence numbers
 - No retry in Go RPC code (*i.e.* will **not** create a second TCP connection)
- However: Go RPC returns an error if it doesn't get a reply
 - Perhaps after a TCP timeout
 - Perhaps server didn't see request
 - Perhaps server processed request but server/net failed before reply came back

RPC and Assignments 1 and 2

- Go's RPC isn't enough for Assignments 1 and 2

 It only applies to a single RPC call
 - If worker doesn't respond, master re-sends to another
 - Go RPC can't detect this kind of duplicate
 - Breaks at-most-once semantics
 - No problem in Assignments 1 and 2 (handles at application level)
- In Assignment 3 you will explicitly detect duplicates using something like what we've talked about

Exactly-once?

- Need retransmission of at least once scheme
- Plus the duplicate filtering of at most once scheme
 - To survive client crashes, client needs to record pending RPCs on disk
 - So it can replay them with the same unique identifier
- Plus story for making server reliable
 - Even if server fails, it needs to continue with full state
 - To survive server crashes, server should log to disk results of completed RPCs (to suppress duplicates)
- Similar to Two-Phase Commit (later)

Exactly-once for external actions?

- Imagine that the remote operation triggers an external physical thing
 - -e.g., dispense \$100 from an ATM
- The ATM could crash immediately before or after dispensing and lose its state
 - Don't know which one happened
 - Can, however, make this window very small
- So can't achieve exactly-once in general, in the presence of external actions

Summary: RPC

- RPC everywhere!
- **Necessary** issues surrounding machine heterogeneity
- Subtle issues around handling failures

Next lecture topic: Time and Logical Clocks
